If the central bank follows an interest rate rule, then inflation is likely to be persistent, even when prices are fully flexible. Any shock, whether persistent or not, may lead to inflation persistence. In equilibrium, the dynamics of inflation are determined by the evolution of the spread between the real interest rate and the central bank's target. Inflation persistence can be characterized by a vector autocorrelation function relating inflation and output. This article shows that a flexible-price, general-equilibrium business cycle model with money and a central bank using an interest rate target can account for such inflation persistence.

1. INTRODUCTION

Fuhrer and Moore (1995) characterize inflation persistence in U.S. data using a vector autocorrelation function relating inflation and deviations of output from trend. In the vector autocorrelation function, both inflation and output are highly persistent and there are significant positive cross-correlations between inflation and output. Of course, vector autocorrelation functions, themselves, do not provide evidence about a particular economic structure, but these time-series regularities are often invoked to justify the assumption that systematic monetary policy actions have real effects. The identification problem is difficult and there is no widely accepted solution.

This article shows that a flexible-price, general-equilibrium business cycle model in which monetary policy shocks have almost no real effects can account for inflation persistence if the central bank follows an interest rate rule. If it does, inflation dynamics are determined by the dynamics of the spread between the real interest rate and the central bank's interest rate target. Any shock, whether persistent or not, may lead to inflation persistence if it drives a persistent wedge between this spread. Thus, inflation persistence is expected to be pervasive in any economy where the central bank is using an interest rate rule. The presence of inflation

This article benefited from comments by Jim Bullard, Charles Carlstrom, Mike Dotsey, Mike Pakko, Bob Rasche, Roman Sustek, and participants in seminars at meetings of the Midwest Macroeconomic Association in Atlanta in March 2001 and the Society for Dynamic Economics in Stockholm in June 2001. Please address correspondence to: Finn E. Kydland, Professor of Economics, Graduate School of Industrial Administration, Carnegie Mellon University, Pittsburgh, PA 15213, U.S.A. Tel.: (412) 268-3691. E-mail: kydland@cmu.edu.
persistence, by itself, has nothing to say about whether prices are sticky or flexible, or whether the real effects of monetary policy are large or small.

Based on Gavin and Kydland (1999), our real business cycle model has a shopping time specification for money. There are no sticky prices and there is no limited participation in financial markets. Agents’ decisions in a period are taken only after all shocks are observed. In this model, inflation persistence is sensitive to the degree of interest-rate smoothing and the central bank’s reaction to output. The only exogenous source of persistence is the technology shock. Note, however, that inflation persistence can occur even if there is no persistence in the shocks because the real rate responds persistently to uncorrelated technology shocks.

In the next section, we summarize evidence about inflation persistence, focusing on the period since 1980. We then briefly describe the structure of our model. In the following sections, we use the model to show that inflation persistence can be caused by central banks using an interest rate rule, even in the absence of price rigidities.

2. INFLATION PERSISTENCE

Our approach is to analyze both U.S. data and the artificial data generated by our model following the methodology of Fuhrer and Moore (1995). In Figure 1, we reproduce the output and inflation components of a vector autocorrelation function similar to the one used by Fuhrer and Moore to illustrate some basic characteristics of U.S. data. These autocorrelation functions are derived from a

![Graphs showing autocorrelation functions for inflation and output.](image)

One-standard-deviation error bands are calculated using a bootstrap method with 10,000 draws. Three draws were rejected because the roots of the VAR were unstable.

**Figure 1**

U.S. DATA 1980Q2 TO 2001Q4 VECTOR AUTOCORRELATION FUNCTION
three-variable autoregression including four lags each of output (the deviation of real GDP from a Hodrick-Prescott trend), inflation (the change in the logarithm of the GDP deflator), and the interest rate (the rate on 3-month U.S. Treasury securities). Our time period is different (1980:Q2 to 2001:Q4), but the shapes are similar to theirs. The persistence of inflation and the cross-correlations are dampened relative to those calculated using pre-1980 data. We also present one-standard-deviation bands around the estimated vector autocorrelation functions; the bands are constructed using the bootstrap technique described by Runkle (1987). The standard deviations are calculated from a distribution created with 10,003 draws from the randomized residuals. Three draws were discarded because they resulted in a VAR with unstable roots.

Starting in the upper left-hand corner of Figure 1 and moving right, we see that inflation is persistent and at least one standard deviation above zero out to the ninth lagged quarter. The cross-correlations between inflation and the lagged output gap are positive and at least one standard deviation above zero for six lags. In the bottom left-hand panel, the cross-correlation between output and the lagged inflation rate is positive in the contemporaneous period, but becomes negative at 2 years, and then returns to zero by the third year. Finally, the autocorrelation function for output shows that it is also persistent. The autocorrelation is high at one lag but decays quickly, reaching zero by the fifth quarter.

3. THE ECONOMIC ENVIRONMENT

We investigate the effects of alternative monetary policy rules embedded in a neoclassical growth model with shocks to production technology, shopping time technology, and the monetary policy rule. We include a stochastic shopping time technology so that we will have three independent sources of error in the data sets generated by our model. These data sets will be used to generate vector autocorrelation functions from a three-variable VAR.

3.1. The Economic Structure. Many identical households inhabit the model economy. Each household maximizes

$$E \sum_{t=0}^{\infty} \beta^t u(c_t, l_t)$$

where $0 < \beta < 1$ is a discount factor, $c_t$ is consumption expenditure, and $l_t$ is leisure time. The functional form of the current-period utility function is

$$u(c_t, l_t) = \frac{1}{1 - \gamma} \left[ c_t^{\mu} l_t^{1-\mu} \right]^{1-\gamma}$$

---

Gavin and Kydland (1999, 2000) show that the covariance structure of nominal and real time series is not stable across the October 1979 policy change. Levis and Piger (2003) show that ignoring such breakpoints leads to upward bias in the measurement of inflation persistence.
where \( 0 < \mu < 1 \) and \( \gamma > 0 \) but different from 1. This CES function, with unitary substitution elasticity between consumption and leisure, was chosen because it is consistent with postwar U.S. data in which long-run hours worked per person changed little despite the large increase in real hourly compensation.

The household's stock of capital, \( k_t \), is governed by the law of motion,

\[
k_{t+1} = (1 - \delta)k_t + x_t
\]

where \( 0 < \delta < 1 \), \( \delta \) is the depreciation rate, and \( x_t \) is investment.

The typical agent spends available time, \( T \), in three basic activities: input in market production, leisure, and transaction-related activities such as trips to the bank, shopping, and so on. Larger money balances make the shopping activity less time consuming. By holding more money, households have more time for work and/or leisure. Household time spent on transactions-related activities in period \( t \) is given by

\[
\omega_0 - \omega_{1,t} \left( \frac{m_t}{P_t c_t} \right)^{\omega_2}
\]

where

\[
\omega_{1,t} = \bar{\omega}_1 + \epsilon^d_t
\]

\( m_t \) is the nominal stock of money at the beginning of period \( t \), and \( P_t \) is the price of physical goods relative to that of money. The parameter \( \omega_{1,t} \) of the shopping time technology is equal to its steady-state level plus an innovation, \( \epsilon^d_t \) that is independent and identically distributed with a zero mean and variance, \( \sigma^2_d \). By restricting \( \omega_{1,t} \) and \( \omega_2 \) to have the same sign and \( \omega_2 < 1 \), the amount of time saved increases as a function of real money holdings in relation to consumption expenditures, but at a decreasing rate. Note that in the timing of the model, only money that is brought in from the previous period is available to reduce shopping time.\(^3\)

Leisure in period \( t \) is

\[
l_t = T - n_t - \omega_0 + \omega_{1,t} \left( \frac{m_t}{P_t c_t} \right)^{\omega_2}
\]

where \( T \) is the total time available and \( n_t \) is time spent in market production.

The nominal budget constraint for the typical individual is

\[
P_t c_t + P_t x_t + m_{t+1} + b_{t+1} = P_t w_t n_t + P_t r_t k_t + (1 + R_t)b_t + m_t + v_t
\]

where \( w_t \) is the real wage rate, \( r_t \) is the rental rate of capital, and \( v_t \) is a nominal lump-sum transfer from the government. \( R_t \) is the nominal interest rate earned.

\(^3\) Note that this timing convention is used in Kydland (1989).
on bonds, which are in zero net supply in equilibrium. The government transfers money balances directly to households according to its policy rule. It produces money and conducts policy at zero cost.

Aggregate output, $Y_t$, is produced using labor and capital inputs:

$$Y_t = C_t + X_t = z_t N_t^a K_t^{1-a}$$

where $X_t$ is the total of investment expenditures and $z_t$ is the level of technology, which is subject to transitory shocks. The technology changes over time according to

$$z_{t+1} = \rho z_t + \lambda_{t+1}$$

where $0 < \rho < 1$ and the innovation, $\lambda_{t+1}$, is distributed with a positive mean and with variance $\sigma^2_z$.

A law of motion analogous to that for individual capital describes the aggregate quantity of capital. The distinction between individual and aggregate variables is represented here by lowercase and uppercase letters, respectively. This distinction plays a role when computing the equilibrium of a model with government policy in which the equilibrium is not simply the solution to a stand-in planner’s problem. Competitive factor markets imply that in equilibrium each factor receives its marginal product.

3.2. Monetary Policy. Since the early 1960s, the Federal Reserve has used an indicator of reserve market pressures to guide open market operations. For most of the time since the 1970s, that indicator has been the interest rate on bank reserves, the federal funds rate. By setting a short-term target for the federal funds rate, the Fed automatically supplies reserves to meet unexpected shocks to money demand. We assume that the central bank uses this control over the monetary transfer to implement an interest rate rule of the type suggested by Taylor (1993):

$$R_t^* = \bar{r} + \bar{r} + v_t (\ln Y_{t-1} - \ln \bar{Y}) + v_t (\pi_{t-1} - \bar{r})$$

where $R_t^*$ is the period $t$ nominal interest rate target chosen by the central bank at the beginning of period $t$, $\pi_t = \ln P_t - \ln P_{t-1}$ is the inflation rate, and the bar over a symbol refers to the steady-state value. Taylor’s original specification did not include the lagged interest rate. We also allow for the possibility that the central bank smooths interest rates. We add the following partial adjustment mechanism:

$$R_t = \rho R_{t-1} + (1 - \rho) R_t^* + \epsilon_t$$

where we have also included a policy shock, $\epsilon_t$, that is independent and identically distributed with a zero mean and variance, $\sigma^2_{\epsilon_t}$. This shock is a control error that occurs at the beginning of period $t$. 
3.3. Competitive Equilibrium. A competitive equilibrium is achieved when the households and firms solve their optimization problems and all markets clear. Due to constraints, the agent’s choice of any four variables—say, leisure, consumption, investment, and nominal borrowing/lending—will determine the others by means of individual budget and time constraints. Therefore, there are only four unique first-order conditions that can be derived from the agent’s optimizing behavior. The first can be considered as arising from the intratemporal choice between leisure and consumption:

\[
\frac{\partial u}{\partial l}(c_t, l_t) \left( 1 + w_t \omega_1, \omega_2 \left( \frac{m_t}{P_t c_t} \right)^{\omega_2} \frac{1}{c_t} \right) = w_t \frac{\partial u}{\partial c}(c_t, l_t)
\]

This expression is complicated by the fact that the agent’s time spent at leisure is dependent on his time spent shopping, which in turn depends on consumption. If we define \( \kappa_t = 1 + w_t \omega_1, \omega_2 \left( \frac{m_t}{P_t c_t} \right)^{\omega_2} \frac{1}{c_t} \), then, in the absence of shopping time, \( \kappa_t = 1 \) for all \( t \) and this condition is the standard condition equating the ratio of marginal utilities of leisure and consumption to the real wage rate.

In this model there are three ways of substituting consumption across time. One is through investment in capital, one is through holding money, and one is by holding bonds. The first of these intertemporal substitution conditions is

\[
\frac{\partial u}{\partial c}(c_t, l_t) = \beta E_t \left[ \frac{\kappa_t}{\kappa_{t+1}} \frac{\partial u}{\partial c}(c_{t+1}, l_{t+1})(r_{t+1} + 1 - \delta) \right]
\]

Again, note that in the absence of shopping time, this first-order condition becomes the familiar expression equating the ratio of expected marginal utilities to the gross real interest rate.

Next, we have the first-order condition associated with the choice of money balances. It can be written as

\[
\frac{\partial u}{\partial c}(c_t, l_t) = \beta E_t \left[ \frac{\kappa_t}{\kappa_{t+1}} \frac{P_t}{P_{t+1}} \left( 1 + \frac{P_{t+1}c_{t+1}}{m_{t+1}} (\kappa_{t+1} - 1) \right) \frac{\partial u}{\partial c}(c_{t+1}, l_{t+1}) \right]
\]

Written in this way, we can see that if there are no shopping time costs, then the ratio of expected marginal utilities is equal to the expected real return on that asset. In the case of money, the return is the inverse of the gross inflation rate, or \( P_t / P_{t+1} \).

Finally, the first-order condition associated with buying or selling bonds is given by

\[
\frac{\partial u}{\partial c}(c_t, l_t) = \beta E_t \left[ \left( 1 + R_{t+1} \right)^{-\frac{\kappa_t}{\kappa_{t+1}}} \frac{P_t}{P_{t+1}} \frac{\partial u}{\partial c}(c_{t+1}, l_{t+1}) \right]
\]
Once again we note that, in the absence of shopping time costs, this first-order condition reduces to the familiar one where the ratio of marginal utilities has been set equal to the real return to holding bonds.

To analyze the quantitative implications of our model, we use the computational method described by King and Watson (1998). The transition equation for the nominal interest rate is given by the bank’s interest rate rule. In equilibrium, aggregate output and the money stock must be consistent with individual choices. The price level is determined in equilibrium by forcing bonds to be in zero net supply. Linearizing first-order conditions, transition equations, and equilibrium conditions around steady-state values results in the approximation that represents our model in the experiments below.

4. MONETARY POLICY EXPERIMENTS

Table 1 summarizes the baseline calibration used in the experiments. Information about deviations from this baseline case is given in the text and figures when appropriate. The calibration is based on empirical estimates of steady-state relations among the model’s variables. Most of the estimates come from long-run or average values. Measurements from panel data also are used.

The parameter $\beta$ in the production function is the model’s steady-state labor share of output and is set equal to 0.65. This is in line with estimates obtained for the United States if approximately half of proprietors’ income is considered to be labor income. We use a quarterly depreciation rate of 0.025. Persistence in the technology shock is assumed to be 0.95 and the standard deviation of the technology shock is set equal to 0.0075—values in line with those estimated by Prescott (1986).

</table>
Turning to the household sector, the annual real interest rate is 4%, yielding a quarterly discount factor, $\beta$, of approximately 0.99. The risk-aversion parameter, $\gamma$, is set equal to 2, which means more curvature on the utility function than that corresponding to logarithmic utility. This value is in the range of results reported by Hansen and Singleton (1983) and Neely et al. (2001).

We calibrate the money-time trade-off by setting $\omega_2$, the curvature parameter, equal to $-1$. This implies a long-run money demand function with interest elasticity equal to $-0.5$, consistent with the empirical evidence in Hoffman and Rasche (1991), Lucas (2000), and Mulligan and Sala-i-Martin (1997). With the steady-state output and money stock normalized to unity, the steady-state price level is determined by setting the annual income velocity of money at 6.7—equal to the average of M1 velocity between 1980 and 2001. We assume zero real economic growth and zero money supply growth in the steady state, so the steady-state inflation rate is also zero.\footnote{M1 is adjusted for the introduction of sweep accounts after 1994. See Anderson and Rasche (2001) for a discussion of these accounts and the need for adjusting M1.} Given the price level, we derive $\hat{\omega}_1$ from the household’s first-order condition for the choice of money holding. The implied steady-state value of $\hat{\omega}_1$ is $-0.0022$. The magnitudes of $\hat{\omega}_1$ and $\omega_2$ can be understood through a marginal evaluation around the average. If the real money stock is increased by 1\% relative to its steady state, then a household’s resulting weekly time saving is less than a minute. The standard deviation of the payments technology shock is set so that, when it is scaled by the level of payments technology, it is equal to 0.0025.

Without loss of generality, we normalize steady-state shopping time to zero and choose time units so that $n + l = 1$. In line with the panel-data estimates of Ghez and Becker (1975), we set $n = 0.3$. The remaining parameter $\mu$, the share of consumption in the utility function, usually is determined from the condition $MU_c/MU_t = w$ and usually turns out to be close to $n$ in magnitude. In this case, because of the dependence of time (and therefore $l$) on $m/Pc$, the corresponding condition can be written as

\begin{equation}
\frac{MU_c}{MU_t} = \frac{1}{w} + \frac{\hat{\omega}_1 \omega_2}{c} \left( \frac{m}{Pc} \right)^{\omega_2}
\end{equation}

The implied value for $\mu$ is 0.33. Because the scale of $\hat{\omega}_1$—and the second term in Equation (16)—is small relative to $1/w$, the addition of the shopping time feature has only a tiny effect on the calibration of $\mu$.

The parameters of the Taylor rule are not precisely estimated in the literature. We used Taylor’s value for the weight on inflation (1.5). The covariance structure of output and inflation are not very sensitive to alternative values of this parameter. However, the covariance structure is sensitive to the weight on output. Kozicki (1999) uses a wide variety of measures of inflation and output for the United States during the period from 1983 to 1987 to estimate alternative weights in Taylor-type
rules. She reports a range of values for the output weight between $-0.025$ and $0.1$. Using a model similar to ours, Dressler (2003) estimates the weight on output to be negative, but small and not statistically significant. Using both sticky- and flexible-price models, Ireland (2002) estimates values for the weight on output that are negative, close to the bottom of the range found by Kozicki. We found that a zero weight results in the positive correlation between output and inflation that we observe in the data.

If we do not apply some interest-rate smoothing, then inflation is much more persistent than estimated in post-1980 data. Clarida et al. (2000) and Sack and Weiland (2000) estimate the interest-rate smoothing parameter to be in the range of 0.7–0.8. Rudebusch (2002) argues that it should be much lower. We chose a degree of interest-rate smoothing (0.5) that, in conjunction with a zero weight on output and our assumed shock variances, led to a first-order autocorrelation of inflation that was about 0.5. The standard deviation of the monetary policy shock is assumed to be 0.125, or 50 basis points per quarter at annual rates.

4.1. *Baseline Case.* In Figure 2, we report the vector autocovariance function of output and inflation using the baseline policy rule. As discussed above,
the policy rule was calibrated so that the first-order autocorrelation for inflation is about 0.5. Both the cross-correlation of inflation with lagged output and the cross-correlation of output with lagged inflation are positive at short horizons. The autocorrelation in output also looks much like U.S. data because the technology shock process is calibrated using time-series properties of the Solow residual. Contrary to the U.S. data, patterns of the cross-correlations between inflation and output appear to be backwards; that is, the model cross-correlations of inflation with lagged output becomes negative after about a year, whereas in data they remain positive for about two years. The model cross-correlations of output with lagged inflation remain positive for about two years, whereas in the data they become negative at about one year. This occurs because the trough in the price level leads the peak in the output cycle in the data, but lags in our model. But, as Cooley and Hansen (1995) showed, that is also true in sticky-price models.

4.2. Stabilizing Inflation. Inflation persistence is not sensitive to \( \nu_\pi \), the weight on inflation, as long as the weight is large enough to avoid indeterminacy. Using an analytically tractable model with some features similar to ours and zero weight on output in the policy rule, Carlstrom and Fuerst (2001) show that there are real indeterminacies for values of \( \nu_\pi \) less than unity.\(^7\) Numerical analysis confirms that this is the case for our model when there is no weight on output. When the \( \nu_y = 0.125 \), indeterminacy exists when \( \nu_\pi \) falls below 1.061. The region of indeterminacy lies below a curve that is approximately linear from \((\nu_\pi, \nu_y) = (1,0)\) to \((\nu_\pi, \nu_y) = (1.061, 0.125)\).

In our experiments with the baseline model but with alternative weights on inflation, we found that both the first-order autocorrelation \( (\phi_1) \) for inflation and the cross-correlation between inflation and output were relatively insensitive to values of \( \nu_\pi \) between 1.2 and 3. In all our experiments, a draw was discarded if it resulted in an estimated VAR with unstable roots. This occurs more often as we get closer to the region of indeterminacy.

4.3. Output Stabilization. The inflation autocorrelations are more sensitive to the weight on output than they are to the weight on inflation. Figure 3 reports the results of experiments in which we set the weight on inflation at 1.5 and vary the weight on output between plus and minus 0.125. With \( \nu_y = -0.125 \), \( \phi_1 \) is 0.80. It declines to a minimum value of 0.54 as \( \nu_y \) is raised toward zero. Then it rises quickly to a plateau at 0.90 as \( \nu_y \) is raised further. Given the other baseline parameters, variance of the inflation rate is minimized for values of \( \nu_y \) near 0.025. The VARs appear to be most stable when there is no weight on output.

The positive correlation between inflation and output in U.S. data has been broadly interpreted as evidence that monetary policy has large real effects. Figure 4

\(^7\) Their case that is closest to ours is the cash-in-advance specification for money demand with a backward-looking rule. There are still important differences in the utility function and the timing of the household's access to the bond market that affect the pricing of the nominal interest rate and the conditions for real determinacy.
shows how the cross-correlation is influenced by the weight on output in the policy rule. The correlation is positive, about one-half, if there is no weight on output or if the weight is negative. For positive values of \( \nu_y \), the correlation eventually becomes negative.
4.4. Interest-Rate Smoothing. In preparing for this study, we thought that interest-rate smoothing would be important. Dotsey (1999) uses a model with sticky prices to show that the output effects of a monetary policy shock are greatly amplified with interest-rate smoothing. He also found that inflation persistence may disappear if the central bank smooths interest rates. In this flexible price model, the main effect of adding interest-rate smoothing is to reduce inflation persistence.

Figure 5 reports the results of experiments in which we vary the weight on the lagged interest rate, $\rho_R$, between 0 and 1. With the baseline calibration for other parameters, raising $\rho_R$ from 0 to 1 reduces the first-order autocorrelation from above 0.9 to 0. Even if there is no persistence in technology shock, the first-order autocorrelation will be above 0.9 if there is no interest-rate smoothing. Inflation persistence drops more quickly the more interest rates are smoothed if there is no persistence in the technology shock. Interest-rate smoothing tends to make VARs from the experimental data unstable as $\rho_R$ approaches unity. The model is undetermined at $\rho_R = 1$.\footnote{There is a region of indeterminacy in our model for the baseline model with interest-rate smoothing for values of $\rho_R$ between 1 and 5.18.}

5. Impulse Responses

In this section, we report impulse responses to a 1% shock to the level of technology. We do not show the response of output because it is insensitive to
changes in the policy rule. This approximate neutrality results because a realistic calibration of the shopping time function does not make money holdings large enough to matter for output fluctuations. The response of output follows a pattern familiar in RBC models. A positive technology shock raises output by more than the size of the shock because hours worked also increases. High persistence in the technology shock causes output to remain well above the steady state for many years. The path for output is largely independent of the policy regime. The response of the price level, however, is not. This is important for understanding the effects of putting weight on output in the policy rule. Therefore, we focus on two policy rules in this section. One is our baseline case. The other is the baseline case except that we set the coefficient on output to 0.125, the value implied for our quarterly model by Taylor’s original specification that used annual rates for the interest rate and inflation.

Figure 6 shows the impulse responses of the price level to a positive technology shock. In the baseline case, the price level rises, but only slightly. In the case with a large weight on output, the price level declines smoothly. The inflation dynamics can be seen more clearly in Figure 7, which shows the interest and inflation rate responses to technology shocks under these two cases. Except for the one-period delay in the policy reaction, the interest rate and inflation responses are very similar. It is interesting to note that putting more weight on output does not mean that interest rates rise in response to a technology shock. In this model the opposite occurs because of the dynamic interactions between output and inflation.

However, monetary policy can be important for the real economy if the central bank chooses a policy rule that leads to real indeterminacy.
At first glance, it may appear unusual that putting more weight on output causes the response of the nominal interest rate to a technology shock to become negative. The dynamic response can be understood by thinking about what happens with a fixed money stock. In a model like ours but with a fixed money stock, a 1% shock to technology leads to about a 0.3% decline in the price level. The one-time decline in the price level is unexpected and, by itself, does not affect nominal interest rates. The price level then very gradually rises back to the steady state (inflation is slightly above the steady-state rate). Since output and the price level move in opposite directions, putting a large weight on output has the effect of muting the effect of interest rate policy on stabilizing inflation. Under the Taylor rule, on impact, the price-level response to a technology shock looks more like it would under a fixed money rule. When there is no weight on output, the public knows that interest rate policy is aimed at stabilizing inflation. In effect, the interest rate rule is a promise to provide money growth in a manner that prevents the need for price jumping. Consequently, the price level does not have to fall in the period of the shock.

Figure 8 shows how the money stock responds to a positive technology shock. When the central bank is following the Taylor rule with a large coefficient on output, a technology shock is associated with a simultaneous reduction in the inflation rate. In the next period, the central bank responds by lowering the interest rate about 20–25 basis points. This is associated with a large jump in the money stock. This is consistent with the central bank’s need to deliver a long period of inflation slightly below the steady-state rate. The real interest rate will remain
above its steady state, while the nominal rate remains below the steady state. When there is no weight on output, the result is opposite, but muted. The money supply falls slightly in the period when the central bank raises the interest rate. In this case the nominal rate stays slightly above the real interest rate for an extended period so that the equilibrium requires a long period of inflation slightly above the steady state. In this model, setting the weight on output equal to 0.025 essentially eliminates any effect of a technology shock on inflation or the market interest rate.

6. CONCLUSION

Inflation persistence has been considered evidence against flexible-price, general-equilibrium models because it is nearly impossible to generate inflation persistence in these models if the central bank is following an exogenous money supply rule. Most of the quantitative work on the cyclical effects of monetary policy in these models was done using such money supply rules. We show that it is quite easy to generate inflation persistence in flexible-price models if the central bank is following an interest rate rule.

The key to understanding inflation dynamics under interest rate targeting rules is to understand how the central bank is managing the short-term nominal interest rate relative to the real interest rate. Any policy that induces a persistent difference between the nominal and real interest rates will also induce inflation persistence. There is also a substantially lower variance of inflation in models with interest rate rules than in models with a fixed money stock or exogenous money supply rules. In the case of the fixed money stock, the fluctuations in the price level are driven
mainly by fluctuations in real output. In the case of interest rate rules, they are
driven by fluctuations in the spread between nominal and real interest rates.
